

Online Appendix

This online appendix of the monograph entitled “Effektive Schulsteuerung? Bilanz einer globalen Reformagenda” is divided into four parts. In part A, we provide a definition of variables included in the regression analysis and the robustness checks. In part B, we continue with descriptive statistics. Part C contains the full regression tables referred to in the monograph. In part D, we introduce regression diagnostics and metrics, namely the Variance Inflation Factor (VIF) and the Shapiro-Francia W' Test. For data preparation and calculation procedures, we used the R version 4.3.2, RStudio version 2024.4.2764, and the packages listed in table 1 (with version number and purpose of application). The workflow is depicted in figure 1 and provides an overview of the steps taken to preprocess and analyze the OECD PISA data.

Table 1: Overview of the R packages, including version number and intended purpose, which were used for data preparation and calculations.

R package	Version number	Intended Purpose
haven	2.5.3	Read the OECD SPSS-files for the PISA 2000 wave
EdSurvey	4.0.4	Download the OECD data for PISA waves 2009 and 2015
xlsx	0.6.5	Package used to read and write excel files
tidyverse	2.0.0	Data preprocessing and data frame construction
dplyr	1.1.3	
stringr	1.5.0	
purrr	1.0.2	
reshape2	1.4.4	Convert wide format of PISA-data frame to long format and vice versa
psych	2.3.9	Used to generate a wide range of descriptive statistics
BIFIEsurvey	3.5.19	Employed to impose the OECD weighting scheme on the data and to impute the PISA scores in math, reading, science, and the overall score
lme4	1.1.34	Used to calculate multilevel linear regression models
nortest	1.0.4	Used to test for the violation of the normality of the error terms assumption
performance	0.10.8	Used to calculate Snijders and Bosker's R^2 and ICC-values for all multilevel linear regression analyses
stargazer	5.2.3	Generate a table output of descriptive statistics and regression models
ggplot2	3.4.4	Used to design and visualize graphics based on the calculations
dotwhisker	0.8.2	Used to visualize an effect plot of the main effects provided by the multilevel linear regression models
effect	4.2.2	

Figure 1: Workflow employed to preprocess and analyze the OECD PISA data.

A Variables Included in the Regression Analysis

We used the imputed mean PISA score as dependent variable to avoid bias in the estimation of the association between independent variables and the PISA scores. The calculation of the mean PISA score was as follows. In each wave under scrutiny (2000, 2009, 2015), the PISA test was split into different question clusters (e. g. S1 to S5 for science, M1 to M5 for mathematics and R1 to R5 for reading in 2000). Not every question cluster was administered to every student. Instead, multiple imputation methods were applied to estimate whether a student might have given correct answers in unadministered question clusters. The basis for the imputation was a latent regression model with social context variables as predictors (OECD, 2017, pp. 145–149 and 181–182). Following this step, a principal component analysis was conducted to remove collinearity among variables where present. Finally, weighting schemes on school and student level were applied to provide means to calculate the standard errors of estimators correctly and to calculate sampling variance (OECD, 2017, pp. 116-126). To do so, the OECD applied a balanced repeated replication with Fay’s method (Judkins 1990) and provided 80 separate data matrices and grouped schools with similar characteristics. Based on this calculation, five plausible values for the science, reading, and math scores were predicted in 2000 and 2009, and 10 in 2015. Using the R-package BIFIEsurvey (Robitsch and Oberwimmer, 2019), we first calculated the mean plausible values for each subject and then imputed the scores to attain the final mean PISA scores which were then used as dependent variable.

For measuring the socioeconomic background of students and schools, we used the Index of Economic, Social, and Cultural Status (ESCS). The ESCS is a measure designed to capture the socioeconomic status of a household and relates it to measured student performance in the PISA test. According to Avvisati (2020, p. 3), it is defined as follows:

"ESCS is a measure of students' access to family resources (financial capital, social capital, cultural capital and human capital) which determine the social position of the student's family/household."

ESCS is a composite variable generated by a factor analysis on the parents' highest occupational status, a parent's highest level of education, and home possessions reported by the students. These are possessions that indicate material well-being (e.g., availability of one's own room), cultural affinity (availability of a musical instrument, classical literature, paintings), and educationally relevant resources (e.g., a quiet place to study). In addition, the number of available books in the household is also included in the calculation of the ESCS. Mathematically, this is the summation of the parents' highest occupational status, their highest educational attainment, and home possessions which are divided by the eigenvalue of the first factor generated by the factor analysis (OECD, 2017, pp. 339–340). In the process, the possessions captured by the home possession items changed slightly. For example, in later waves, students were asked about the availability of their own computer for school work or for general use, and other variables were added from 2009 onward (OECD, 2012). The ESCS variables were weighted based on the previous waves, so that at least a rough comparability is given, and they must be interpreted with due caution.

The school-level ESCS was constructed by calculating the mean of the student-level ESCS. The calculation was based on all students sampled for the respective school.

We furthermore included migration background (second generation) and language spoken at home to address the association between a family’s migration background and the PISA score.

The indices of leadership, autonomy, and accountability, included in the models, were calculated as follows for the respective years:

2000:

Leadership is constructed as the proportion of the answer “principal” when asked about responsibility for 12 decision-making competencies.

Autonomy is defined as the ratio of mentions of “principal” and “teachers” to “regional or local education authority” and “national education authority” for items on responsibility for the following six decision-making competencies: hiring teachers, firing teachers, setting entry-level teacher salaries, increasing teacher salaries, formulating school budgets, allocating school budgets.

Accountability is constructed as additive index of “yes” responses to the six questions on control functions (ranged 0–6, listwise deletion of missing values).

2009:

The leadership scale “is based on fourteen items. Positive WLE scores on this index indicate greater involvement of school leadership in school affairs.” (OECD, 2012, Items SC26Q01–SC26Q14).

Autonomy is defined as the ratio of mentions of “principal” and “teachers” to “regional or local education authority” and “national education authority” for items on responsibility for the following six decision-making competencies: hiring teachers, firing teachers, setting entry-level teacher salaries, increasing teacher salaries, formulating school budgets, allocating school budgets.

Accountability is constructed as additive index of “yes” responses to the eight questions on the use of tests for control functions (ranged 0–8, listwise deletion of missing values).

2015:

Leadership is constructed using the SC009 item battery which included 13 items on school leadership. According to the PISA technical report 2015, “The results provided data for five scaled indices. Principals were asked to indicate the frequency of the listed activities and behaviours in their school during the last academic year. The six response categories were ‘did not occur’, ‘1-2 times during the year’, ‘3-4 times during the year’, ‘once a month’, ‘once a week’, to ‘more than once a week’. The overall scale for leadership (LEAD) consists of all 13 items. Table 16.53 shows the item wording, international item parameters and item fit for LEAD.” (OECD, 2017, p. 324)

To calculate school autonomy, the PISA index of school autonomy (SCHAUT) is applied: „The index of school autonomy (SCHAUT) is calculated as the percentage of tasks included in SC010 (yes/no questions) for which the principal, the teachers or the school governing board have considerable responsibility.” (OECD, 2016, p. 243).

Accountability is constructed as additive index of disjunctions containing "yes" responses of items of use of standardized or individual teacher-designed tests for various control functions (ranged 0–6, listwise deletion of missing values).

B Descriptive Statistics

We continue with the descriptive statistics of the variables included in the regression models and provide the point estimates and dispersion of the variables in tables B1-B12. Tables B1-3 refer to the UK, B4-6 to Germany, B7-9 to Sweden, and B10-12 to Finland. As point estimates, we calculated the minimum, mean, maximum, and median. Skewness and kurtosis were calculated to depict the dispersion of the dependent and independent variables included in our regression models. We furthermore included heatmaps depicting the correlation among each variable included in the model or robustness checks in figures B1-B12. Like the tables, figures B1-3 refer to the UK, B4-6 to Germany, B7-9 to Sweden, and B10-12 to Finland. Note that the data for UK (tables and figures 1-3) does not include Scotland.

Table B1: Descriptive statistics of the independent and dependent variables used for the regression models for UK in 2000. Own calculations.

C Regression Models

In a next step, we present the regression models calculated in tables C1 to C12. Note that due to imputations, every variable and goodness of fit measure yields significance values. If, for example, the R^2 values yield no significance, then we have to assume that these values are equal to zero and consequently that the model under scrutiny does not exhibit any variance explanatory power. As every ICC value calculated differs significantly from zero, we further assume that our multilevel models perform better compared to linear regression models. Tables C1-C3 report the results of the multilevel regression analysis for UK, C4-C6 for Germany, C7-C9 for Sweden, and finally, C10-C12 for Finland.

D Regression Diagnostics

Technically, the multilevel linear regression models follow the same assumptions as linear regression models (Korendijk et al., 2008). These are linearity of the independent variables, normality of error terms, homoscedasticity, and independence of observations.

Beginning with the latter, we cannot guarantee independence of observations on student level. As the students are cluster sampled, meaning that only whole classes were included in the PISA test, we used a two-level model to account for the assumption of independency of observations (Maas & Hox, 2005, p. 87). As the tested students are part of the same class taught by the same teachers, students have an impact on each other and values of variables such as disciplinary climate in classes may be determined by test design. In other words, this approach allows the residuals of the students to be correlated with the values of the student level variables and with school level variables. This in turn allows us to calculate two error terms (one on student level and one on school level) and thus to explain the portion of variance explained by a regression model on student as well as on school level (Snijders und Bosker, 1994).

We used the variance inflation factor (VIF) to test for heteroscedasticity of our models. To accomplish this, we programmed an own function to calculate the VIF for the two-level models used by the BIFIEsurvey package called `vif_calculator`. The VIF regresses each independent variable of a model under investigation on the standard errors of a regression model containing all other variables. For example, in a model with PISA science scores as dependent variable, the student's ESCS, the average ESCS at school, and the disciplinary climate at school, the VIF would test if the student's ESCS could predict the residuals of a regression model consisting of the average ESCS and the disciplinary climate. This procedure is then repeated for every independent variable.

Mathematically, the VIF is calculated for each variable separately by dividing 1 by $1-R^2$ for each regression with one of the independent variables included as dependent variable, whereas the rest acts as independent variable in this regression. The VIF is minimal at a value of 1 (no multicollinearity) and gets larger the more variance of the error terms is explained by a single variable (O'brien 2007). A VIF under 4 indicates low levels of multicollinearity, values between 4 and 10 are associated with medium levels of multicollinearity, and values over 10 indicate high levels of multicollinearity. If at least one variable achieves values over 10, chances are high that confidence intervals of the regressors (β) are miscalculated. A miscalculation of confidence intervals in turn renders the significance level unreliable. We might therefore either miss significant associations between independent variables and the PISA mean score, or worse, might understand associations wrongly.

The VIF, however, is a measure for multicollinearity for single level linear regression models. Therefore, variables associated with the school level may show very high values or may be multicollinear on a single level but not on the two levels included in our calculations. The VIF-values are reported in tables D1 to D12 for each model separately. The findings are reported in the same order as the descriptive statistics and regression analyses in appendix B and C. Overall, the models performed well and showed a low degree of multicollinearity with values < 4 , with the exception of model 3 for Sweden 2000, models 3 and 7 in the case of Finland 2009 and model 3 for Finland 2015.

Finally, we conducted Shapiro-Francia W' tests to account for the normality of the error terms assumption (Royston 1993; Thode Jr. 2002). We have to make sure that the normality of error terms of our models holds, as nonnormally distributed residuals (e.g., bimodal, multimodal) yield the danger of inaccurate prediction intervals (standard errors) of the independent variables (β). Therefore, our models might lead to miscalculated significance values. Additionally, the association between our dependent variable (PISA score) and our independent variables might not be linear.

As the BIFIE-survey package does not provide a prediction function and to extract error terms, we coded an own function using the following routine: First extract the beta values included in the models. Second, predict the values for each student based on the predictor values. Third, subtract the predicted values from each plausible value which are the basis of our regression models (e.g., the first mean plausible PISA score, the second etc.). Fourth, calculate the mean deviation from all given plausible values. At last, check if the number of observations is below or equal 5000. As the Shapiro-Francia W' test is specified for up to 5000 observations, we decided on drawing a sample of 5000 residuals as calculated above from our population if the number of observations exceeds this limit. Otherwise, the Shapiro-Francia W' test would yield biased estimates.

The null hypothesis (H_0) of the Shapiro-Francia W' test assumes that the residuals of a variable under consideration follow a normal distribution, whereas the alternate hypothesis (H_A) assumes that the residuals do not follow a normal distribution. Higher values of test statistics W and V indicate a violation of the normality assumption. Mathematically, the V value is like z -statistics in hypothesis testing. Therefore, the higher the V , the lower the p -value¹, as reported in the last column of tables D7 to D12, the more likely the residuals are not normally distributed. If a value of $p < 0.05$ is reported, the probability to reject H_0 albeit H_0 is true is less than 5% and the residuals of the respective variable follow most likely not a normal distribution.

As seen in tables D13 to D24 in the p -value column, the normality assumption is violated in most cases. This is possibly caused by our large sample sizes, as the Shapiro-Francia W' test tends to be more sensitive to violations of the normality assumption when the sample size increases. However, we decided to account for this possible violation by applying a heteroscedastic corrected covariance matrix estimation (Pek et al., 2018), also known as Huber-Sandwich estimator or robust standard errors (Freedman, 2006). Robust standard errors use the squared residual values for each observation instead of the constant and independent error terms usually applied in linear regression models. By doing so, we widen the confidence interval of the regressions considerably and allow variables to become insignificant more easily and to account for nonnormally distributed independent variables.

¹ Please note that the E in the p -value column translates to “exponent”. For example, 3.57E-12 denotes $3.57 \cdot 10^{-12}$.
